Draft version March 30, 2018

ABSTRACT

We present results of a study comparing the relative velocity of Ly α absorbers to the rotation direction and velocity of nearby galaxy disks. We find...

Subject headings: galaxies:intergalactic medium, galaxies:evolution, galaxies:halos, quasars: absorption lines

1. INTRODUCTION

Our current Λ CDM cosmology picture describes galaxies forming hierarchically out of overdensities in the underlying dark matter distribution. As matter is funneled toward a growing galaxy, conservation of angular momentum redistributes the angular momentum in this gas to match that of the halo and underlying dark matter as the gas is shock-heated and slowly cools. As this infalling gas is responsible for birthing and continuing to feed the galaxies, it is expected that the extended gaseous halos should rotate in the same sense as both the galactic disks and dark matter halos. Galaxy rotation curves have been observed to extend at constant velocity out to... (cite...). It becomes increasingly difficult to measure gas rotation much farther from this however as the density rapidly decreases. Within this region the galaxy disks transition into circumgalactic medium (CGM), and eventually the CGM merges with the intergalactic medium (IGM). At what point, however, does the surrounding medium cease to circulate with the galaxy?

HYDRO? simulations such as those by Stewart et al. (2011, 2013) suggests that the bulk CGM kinematics out to (WHAT DISTANCE) may circulate, and that absorption in intervening QSO sightlines should be able to accurately capture this rotation signature. Observational confirmation, however, has been inconclusive. Côté et al. 2005 probed the halos of nine galaxies using *HST* observed background QSOs, finding large warps would be needed to explain the velocity of *Hi* absorbers by an extended rotating disk. Wakker & Savage (2009) compiled a sample of 4 galaxy-QSO systems from the literature, finding only 1/4 of Ly α absorbers appeared to co-rotate with the associated galaxy disk. Approaching the question from a different angle, Bowen et al. (2016) probed the halo of a single galaxy, NGC1097, with 4 nearby QSO sightlines, and suggests that an extended, slowly rotating disk with additional inflowing IGM material best matches observations.

Numerous studies have shown a correlation between equivalent width and decreasing velocity difference between galaxies and IGM absorbers (e.g., French & Wakker 2017, MORE).

To make progress here, we have obtained rotation curves for 12 nearby spiral galaxies which are located within 500 kpc of a background QSO observed by the Cosmic Origins Spectrograph (COS) on *HST*.

We have augmented this new sample with additional galaxies with known rotation velocity and orientation

from the literature. In Section 2 we describe the selection and reduction of both SALT and COS spectra. We then discuss each galaxy-QSO system in detail in Section 3, and introduce our halo-velocity model for interpreting these systems in Section 4. In Section 5 we discuss the overall results of this exercise and present a physically-motivated interpretation of these results. See Section 6 for a summary of our results and conclusions.

2. DATA AND ANALYSIS

2.1. SALT Data

Our sample contains 12 galaxies observed with the Southern African Large Telescope (SALT) Robert Stobie Spectrograph (RSS) in longslit mode. These 12 were selected from a larger pool of 48 submitted targets by the SALT observing queue. These 48 possible targets were chosen for their proximity to background QSOs whose spectra contained promising Ly α lines. Finally, we only included galaxies with $z \leq 0.33$ ($cz \leq 10,000$ km s⁻¹), angular sizes less than 6' to enable easy sky subtraction without taking additional exposures, and surface brightnesses sufficient to keep exposure times below ~ 1300 s. Table 2 summarizes these observations. Data was taken for 2 additional galaxies, NGC3640 and NGC2962, but proved unusable due to issues with spectral identification and low signal-to-noise (respectively).

All SALT galaxy spectra were reduced and extracted using the standard PySALT reduction package (CITATION), which includes procedures to prepare the data, correct for gain, cross-talk, bias, and overscan, and finally mosaic the images from the 3 CCDs. Next, we rectify the images with wavelength solutions found via Ne and Ar arc lamp spectra line identification. Finally, we perform a basic sky subtraction using an off-sky portion of the spectrum, and extract 5-10 pixel wide 1-D strips from the reduced 2-D spectrum.

For each 1-D spectrum, we identify the H α emission lines and perform a non-linear least-squares Voigt profile fit using the Python package LMFIT¹. The line centroid and 1σ standard errors are returned, and these fits are then shifted to rest-velocity based on the galaxy systemic redshift and heliocentric velocity corrections are calculated with the IRAF rvcorrect procedure. The final rotation velocity is calculated by then applying the inclination correction, $v_{rot} = v/\sin(i)$. Final errors are

Table 1

COS targets in this sample. *Total exposure time and S/N ratio is given for multi-orbit exposures.

calculated as a quadrature sum of 1σ fit errors, systemic redshift error, and inclination uncertainty as follows:

$$\sigma^2 = \left(\frac{\partial v_{rot}}{\partial \lambda_{obs}} \right)^2 (\Delta \lambda_{obs})^2 + \left(\frac{\partial v_{rot}}{\partial v_{sys}} \right)^2 (\Delta v_{sys})^2 + \left(\frac{\partial v_{rot}}{\partial i} \right)^2 (\Delta i)^2, \quad (1)$$

where $\Delta \lambda_{obs}$, Δv_{sys} , and Δi are the errors in observed line center, galaxy redshift, and inclination, respectively.

We determine the inclination error by calculating the standard deviation of the set of all axis ratio values available in NED for each galaxy. The final physical scale is calculated using the SALT image scale of 0.1267 arc-sec/pixel, multiplied by the 4-pixel spatial binning, and converted to physical units using a redshift-independent distance if available, and a Hubble flow estimate if not. We adopt a Hubble constant of $H_0 = 71 \text{ km s}^{-1} \text{ Mpc}^{-1}$ throughout.

Finally, we calculate our approaching and receding velocities via a weighted mean of the outer 1/2 of each ro-

tation curve, with errors calculated as weighted standard errors in the mean. Our final redshifts are calculated by forcing symmetric rotation, such that the outer 1/2 average velocity for each side matches in magnitude. See Figure 2.1 for an example.

2.2. COS Spectra

The Barbara A. Mikulski Archive for Space Telescopes (MAST) archives yield 19 QSO targets observed by COS which lie within 500 kpc of our SALT galaxies. These targets vary widely in signal-to-noise from approximately 5 to 100 due to our choosing them based only on their proximity to galaxies with known rotation. The reduction procedure for these spectra follow those described by French & Wakker 2017 and Wakker et al. (2015). In short, spectra are processed with CALCOS vXXXX? and combined via the method of Wakker et al. (2015), which helps corrects the COS wavelength scale misalignments produced by CALCOS. Multiple exposures are combined via alignment with Galactic 21cm absorption spectra and summing total counts per pixel before converting to flux. The COS instrument is described in detail by Green et

Table 2

SALT targeted galaxies. Columns are as follows: 1) the galaxy name, 2), 3) R.A., Dec. in J2000, 4) galaxy systemic velocity, 5) morphological type (RC3), 6) RSS grating used, 7) approaching side velocity, 8) receding side velocity, 9) observation date, 10) exposure time, and 11) S/N of the H α or Ca H&K lines.

al. (2012).

3. SALT GALAXIES

3.1. CGCG039-137

CGCG039-137 is an isolated Scd type galaxy with a measured systemic velocity of $6918 \pm 24 \text{ km s}^{-1}$ and inclination of 63° . There are two associated sightlines: RX_J1121.2+0326 at an impact parameter of 99 kpc and azimuth angle of 71° on the receding side, and SDSSJ112224.10+031802.0 at 491 kpc and 24° on the approaching side. Ly α absorption is detected in both sightlines within 400 km s^{-1} of CGCG039-137.

Towards RX_J1121.2+0326 we detect Ly α at 6975 km s^{-1} , which, at $\Delta v = 57 \text{ km s}^{-1}$, lies well within the range of projected velocities consistent with co-rotation. The absorber detected toward SDSSJ112224.10+031802.0 occurs at a more distant 6606 km s^{-1} ($\Delta v = -312 \text{ km s}^{-1}$). Although this absorber has the correct sign for co-rotation (blue-ward on the approaching side of the disk), the large velocity difference and impact parameter make it unlikely that this absorption can be linked to coherent halo rotation.

3.2. ESO343-G014

ESO343-G014 is an edge on spiral galaxy with a measured systemic velocity of $9138.9 \pm 31.7 \text{ km s}^{-1}$. It has a smaller neighboring galaxy, 2MASXJ21372816-3824412, located north of it's major axis at a projected distance of 216 kpc and velocity of 9129. The nearest sightline is towards RBS1768 at an impact parameter of 466 kpc and 74° azimuth angle on the approaching side. We detect 3 Ly α absorption lines within 300 km s^{-1} of ESO343-G014 (at 9308, 9360, and 9434 km s^{-1}). All of these are anti-aligned with the rotation of ESO343-G014, but unfortunately the presence of 2MASXJ21372816-3824412 makes it difficult to attribute this gas solely to ESO343-G014. Additionally, this gas could be attributed to either the approaching or receding side of the disk due to the large impact parameter and high azimuth angle of the sightline.

3.3. IC5325

IC5325 is a face-on SAB(rs)bc type galaxy with a measured velocity of $1511.9 \pm 8.4 \text{ km s}^{-1}$. It's inclination is just high enough (25°) to obtain a reasonable rotation curve. The closest neighboring galaxy is ESO347-G020 to the Southeast at 306 kpc and a heliocentric velocity of 1745 km s^{-1} . Three other much smaller galaxies are also located $\sim 450 \text{ kpc}$ to the Southwest. We detect Ly α absorption at 1598 km s^{-1} , $\Delta v = 86 \text{ km s}^{-1}$ in the spectrum towards RBS2000 at an impact parameter of 314 kpc and azimuth angle of 64° on the approaching side. While this velocity is anti-aligned with the rotation the disk gas, the low inclination angle of IC5325 leads to a highly uncertain position angle. Without additional observations, we cannot say for certain if the location of RBS2000 actually lies on the approaching or receding side. This position angle uncertainty also means our SALT rotation curve is a lower limit on the true rotation velocity of IC5325.

3.4. MCG-03-58-009

MCG-03-58-009 is a massive and very isolated Sc type galaxy at a measured velocity of $9015 \pm 19 \text{ km s}^{-1}$ and inclination angle of 49° . A weak Ly α absorber is detected at 9029 km s^{-1} towards MRC2251-178, which lies 355 kpc away at an azimuth angle of 71° on the receding side. Although this absorber matches the velocity direction expected for co-rotation, the velocity difference ($\Delta v = 14 \text{ km s}^{-1}$) is within the systemic velocity uncertainty. The relative weakness of this absorber ($\text{EW} = 62 \pm 4 \text{ m\AA}$) is somewhat surprising given it's proximity (just outside of $1 R_{\text{vir}}$) to a massive galaxy. If this is representative of an isolated system such as MCG-03-58-009, then we should expect the halo rotational velocity to approach systemic by $1 R_{\text{vir}}$.

3.5. NGC1566

NGC1566 is well sampled (5 nearby QSO sightlines), but unfortunately also part of a complex environment of neighboring galaxies. We detect Ly α in all 5 of these sightlines. The farthest three, HE0439-5254, RBS567, and HE0435-5304, are clustered close together to the northeast of NGC1566 at $\gtrsim 395 \text{ kpc}$ and azimuth angles of $\sim 60^\circ$.

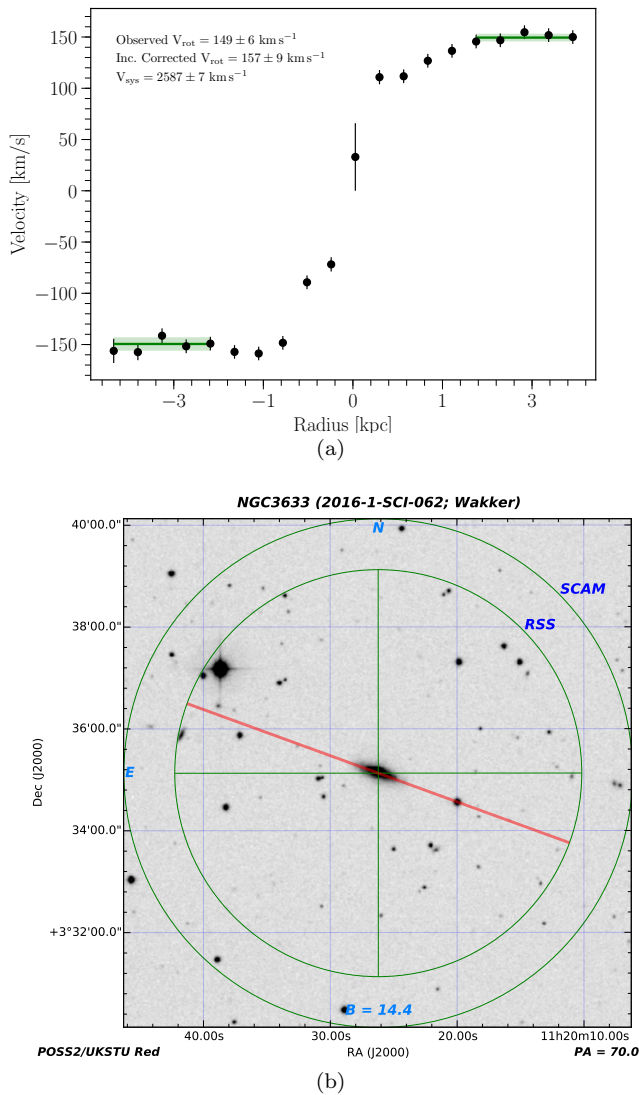

Figure 1. a) Rotation curve of NGC3633. The solid green line indicates the weighted mean velocity over the corresponding x-axis region, and the shaded green indicates the 1σ error in the mean. b) SALT finder chart for NGC3633 showing the position of the slit in red.

HE0429-5343 is in the same direction and azimuth angle but closer at $\rho = 256$ kpc, and shows Ly α absorption at 1167 and 1358 km s^{-1} . These absorbers both have the correct velocity *sign*, but we would expect a smaller velocity for co-rotation (approximately $\Delta v \sim \pm 40 \text{ km s}^{-1}$ projected). This difference could be explained by invoking either a warped extended disk, or perhaps inflowing gas.

1H0419-577 is located to the south at 303 kpc and just east of the receding side of the major axis at an azimuth angle of 10° . We detect Ly α at 1071, 1123, 1188, 1264, and 2020 km s^{-1} , all of which are the wrong sign for co-rotation or distant in velocity. This sightline is actually closer to a small group of galaxies including NGC1549, NGC1546 and NGC1536, all with systemic velocities near 1200 km s^{-1} . We expect the lines at 1071,

1123, 1188, 1264 km s^{-1} to be associated with this group rather than with NGC1566.

3.6. NGC3513

NGC3513 is a mostly face-on SB(rs)c galaxy with heliocentric velocity $V_{\text{hel}} = 1204 \pm 12 \text{ km s}^{-1}$. It has a companion galaxy in NGC3511 at an impact parameter of 44 kpc at $v_{\text{hel}} = 1109 \text{ km s}^{-1}$. We detect Ly α at 1182 km s^{-1} toward background QSO H1101-232, which is located directly south at 60 kpc and azimuth angle of 67° on the receding side. NGC3513 appears to be rotating slowly, with a maximal inclination-corrected rotation velocity of $22 \pm 24 \text{ km s}^{-1}$. The $\Delta v = -22 \text{ km s}^{-1}$ for this absorber matches well with the magnitude of this rotation, but is opposite in sign for co-rotation. Given that NGC3511 is so close, this absorber's velocity is probably subject to a complex velocity field influenced by both NGC3511 and NGC3513.

3.7. NGC3633

NGC3633 is an isolated, edge-on SAa type galaxy at a velocity of $2587 \pm 7 \text{ km s}^{-1}$. Several locations along the disk of NGC3633 show two velocities for emission. We have combined these into a single velocity measurement via a weighted average. There are three nearby sightlines: SDSSJ112005.00+041323.0 is straight north at 468 kpc and 78° azimuth, RXJ1121.2+0326 is to the southeast at 184 kpc and 58° azimuth, and SDSSJ112224.10+031802.0 at 413 kpc and 50° azimuth. Toward RXJ1121.2+0326 we detect a Ly α absorber at 2605 km s^{-1} on the approaching side, which is essentially systemic velocity for NGC3633. The spectrum of SDSSJ112224.10+031802.0 shows absorbers at 2285 and 2578 km s^{-1} , both of which are of the correct sign for co-rotation. We do not detect any Ly α towards the third sightline, SDSSJ112224.10+031802.0.

3.8. NGC4536

NGC4536 is a SAB(rs)bc type galaxy located in a complex environment with many other nearby galaxies. The data on the receding side of NGC4536 is quite messy, and may include contamination from background sources. Hence, our measured systemic velocity of $1867 \pm 33 \text{ km s}^{-1}$, and thus rotation velocity of $139 \pm 37 \text{ km s}^{-1}$, have relatively high uncertainty. Other published redshift values available from NED and rotation velocities from the HyperLEDA database are broadly consistent with our values, albeit biased slightly lower and higher in velocity, respectively.

There are 2 sightlines to the southwest of NGC4536, both on the receding side of the galaxy. HE1228+0131 at 338 kpc and 86° azimuth has 5 Ly α lines: 1495, 1571, 1686, 1721, and 1854 km s^{-1} . None of these are of the correct orientation for co-rotation, and all are more likely to be associated with other nearby galaxies, such as NGC4517A, which is slightly closer to these absorbers in impact parameter and velocity than is NGC4536. The second nearby sightline is toward 3C273 at 344 kpc and 46° azimuth angle, and shows 3 Ly α lines at velocities of 1580, 2156, 2267 km s^{-1} . Two of these are correctly oriented for co-rotation, but are too high in velocity to make this scenario probable. Overall, given the number of nearby galaxies and their locations, we would expect

these absorbers to trace the overall velocity field instead of the halo rotation of any particular galaxy.

3.9. NGC4939

NGC4939 is a large, fast rotating ($V_{rot} = 275 \pm 49$ km s⁻¹) SA(s)bc type galaxy at systemic velocity $V_{hel} = 3093 \pm 33$ km s⁻¹. We detect a single Ly α absorber at 3448 km s⁻¹ towards PG1302-102 at 254 kpc and 61° azimuth angle towards the southeast. This absorber is located on the approaching side of this galaxy, so we can easily rule out co-rotation in this case. NGC4939 does not have any close neighbors, so represents strong case against co-rotation for gas near or past 1 R_{vir} .

3.10. NGC5364

NGC5364 is a SA(rs)bc pec type galaxy at a measured systemic velocity of 1238 ± 17 km s⁻¹. It is located in a group environment with 5 other large, nearby galaxies. The sightline toward SDSSJ135726.27+043541.4 at 165 kpc and 84° azimuth angle contains Ly α absorbers at 1124 and 1296 km s⁻¹ on the receding side. However, because of the orientation of NGC5364 on the sky with respect to this sightline, these absorbers lie extremely close to the inflection point were projected rotation velocities flip to approaching instead of receding. For example, shifting the location of SDSSJ135726.27+043541.4 east by a tenth of a degree (~ 20 kpc) is sufficient to put these absorbers on the approaching side of NGC5364. Hence, both of these absorbers could be co-rotating with NGC5364 given very reasonable assumptions on the shape of an extended disk. Nonetheless, the fact that this system lives in galaxy group environment likely dominates the surrounding velocity field.

3.11. NGC5786

Systemic velocity as published: 2998
Velocity as measured: 2974.6 ± 21.5
Rotation velocity (inc corrected) 172 ± 28 km s⁻¹
Rotation velocity (observed) 156 ± 19 km s⁻¹
Inclination: 63
Adjusted Inc: 65
Morphology: (R'₂)SAB(s)bc
 $L_* = 25$

One sightline:
QSO1500-4140 at 453 kpc, 1deg az:
3141 Ly α (dv = 166 km s⁻¹ on pos side)

3.12. UGC09760

Systemic velocity as published: 2023
Velocity as measured: 2093.7 ± 15.5
Rotation velocity (inc corrected) 46 ± 16 km s⁻¹
Rotation velocity (observed) 46 ± 12 km s⁻¹
Inclination: 85
Adjusted Inc: 90
Morphology: Sd
 $L_* = 0.17$

Two sightlines: SDSSJ151237.15+012846.0 at 123 kpc, 90deg az:
2051 Ly α (dv = -43 km s⁻¹ on minor axis. Looks neg side, but extremely close)

3.13. Ancillary Data

To increase our sample size we have also searched the literature for galaxies with published rotation curves and orientations. Unfortunately, while the rotation velocity is available for thousands of galaxies, only a handful also include the *orientation* of the rotation on the sky. Of these, only XXXX have a systemic velocity greater than ~ 500 km s⁻¹, and are near to a COS or STIS sightline with available data.

3.14. NGC0628

From the THINGS survey (Walter et al. 2008), NGC0628 fits our criteria with a heliocentric velocity of 657 km s⁻¹ and a sightline towards SDSSJ014143.20+134032.0 located at 377 projected kpc away. Although NGC0628 is mostly face-on ($i = 31^\circ$), we were able to extract a rotation curve from the publicly available THINGS first-moment H map.

3.15. NGC3198

NGC3198 is a well studied SB(rs)c type galaxy which is included the detailed THINGS rotation curve study of de Blok et al. (2008). We extracted the raw rotation curve derived by de Blok et al. (2008) using the plot digitization software WebPlotDigitizer². NGC3198 has a systemic velocity of 660 km s⁻¹, and is located 370 kpc away from a sightline toward RX_1017.5+4702 at an azimuth angle of 55° on the approaching side of NGC3198. We detect Ly α absorption in the spectrum of RX_1017.5+4702 at 629 km s⁻¹. NGC3198 has an even and flat rotation curve, with an average velocity of $v_{rot} = 150$ km s⁻¹ **CHECK THIS**. The approaching side is oriented northeast.

3.16. NGC3351

Mazzalay et al. (2014)
778kms - no rot curve yet - close to a big group
IRAS10378+1109 - no data (clobbered by LLS)
3C245.0 - low res only

3.17. NGC5907

- 667kms - Sanders 1996, Allaert (2015A&A...582A..18A) also

² WebPlotDigitizer; <http://arohatgi.info/WebPlotDigitizer>

NW is receding side (Allaert et al. 2015).
Rotation curve data from Yim et al. (2014)

SDSSJ152053.59+571122.1 at 286kpc, (possible line,
messy spectrum)
SBS1503+570 at 413kpc, 47 az (Lya at 708kms)

3.18. *NGC4565*

NGC4565 is an edge on ($i = 75^\circ$ at a heliocentric velocity of 1230 km s^{-1} , for which we have taken the rotation curve and orientation from Sofue (1996).
RX_J1236.0+2641 at 147kpc (Lya at 794, 1009, 1166 kms)

3.19. *UGC06446*

$V_{sys} = 645 \text{ km s}^{-1}$ (R. A. Swaters et al 2009, Verheijen & Sancisi (2001))
MCG9-19-073 at 179kpc - low res only
SDSSJ112448.30+531818.0 at 143kpc, 22 az (Lya at 664kms)
RBS971 at 226kpc, 88 az (clobbered by huge H2 system)
RX_J1117.6+5301 at 417kpc, 52 az (Lya at 685kms)

3.20. *UGC06399*

$V_{sys} = 791 \text{ km s}^{-1}$ (R. A. Swaters et al 2009)
SBS1116+523 at 471kpc, 13.4 az (Lya at 731kms)
MCG9-19-078 at 301kpc (G160M only)

3.21. *NGC3726*

$V_{sys} = 866 \text{ km s}^{-1}$. S side is receding
CSO1208 at 369kpc, 87 az (Lya at 731, 874kms)
PGC139665 at 440, 86 az (G130M but not in reduce)
close to CSO1208

Both sightlines closer to some other little galaxies.
NGC3877 nearby, has rot curve

3.22. *NGC3067*

The galaxy-QSO pair NGC3067-3C232 is a particularly well studied system. They are separated by only 11 kpc (74° azimuth angle) and a LLS of $N_{HI} = 110^{20} \text{ cm}^{-2}$ is detected toward 3C232 at 1421 km s^{-1} ($V_{sys} = 1476 \text{ km s}^{-1}$), which has been postulated as a high velocity cloud (HVC) orbiting NGC3067. We obtained the rotation curve for NGC3067 from Danziger & Chromey (1972) and the orientation from Carilli et al. (1989) (see also Keeney et al. (2005)).

SDSSJ095914.80+320357.0 at 128 kpc, 43 az (no ID'd, but probable line around 1500kms)
RX_J1002.9+3240 at 359 kpc, 33 az (not in reduce yet)

We have also included the 5 galaxy-QSO systems analyzed by Côté et al. (2005). We briefly summarize each of these systems here, and refer the reader to Côté et al. (2005) for a more complete discussion. **ALL? OF THESE GALAXIES WE PROJECT TO BE**

AT GREATER IMPACT PARAMETER THAN COTE DID. MOSTLY BASED ON BETTER RID DISTANCES THAN USED BY COTE

3.23. *NGC6140*

NGC6140 is a small SB(s)cd pec type galaxy located at $V_{sys} = 910 \text{ km s}^{-1}$ and 113 kpc from the sightline toward QSO MRK876. The approaching side is oriented toward the east, with MRK876 toward the northwest at an azimuth of 55° (although this is somewhat uncertain; the position angle for NGC6140 could be closer to 90° than our adopted value of 60° due to it being mostly face on, faint, and strongly barred).

3.24. *NGC4529*

As an inclined, isolated galaxy with a QSO sightline located 159kpc and only 23° off the major axis, NGC4529 represents an ideal test environment for this study. This sightline towards MRK771 contains a Ly α absorber at 2553 km s^{-1} . With $V_{sys} = 2536 \text{ km s}^{-1}$ and MRK771 located on the approaching side of NGC4529 (SW side), this is a clearcut case of counterrotating *H i*. As Côté et al. (2005) conclude, “there is simply no physical way to produce such a velocity with an extending co-rotating disk.”

3.25. *UGC04238*

Rotation curve taken from Côté et al. (2005).
PG0804+761 at 148kpc

3.26. *UGC08146*

Rotation curve taken from Côté et al. (2005).

 target (not in reduce yet)
 SDSSJ112756.70+115427.0 at 320 kpc - (not in reduce
 yet)
 SDSSJ111916.20+110107.0 at 406 kpc - G230L only
 4C12.40 at 451 kpc - G190H, G270H, G230L only

3.30. NGC5951

$V_{sys} = 1780 \text{ km s}^{-1}$. A couple of nearby galaxies
 (NGC5954, NGC5953), but the sightline is closer and
 on the opposite side. Rhee & van Albada (1996)
 2E1530+1511 at 55 kpc, 85 az - (Lya at 1795, 1953)

3.31. NGC7741

$V_{sys} = 750 \text{ km s}^{-1}$. Both UGC12732 and UGC12791
 are closer than the sightlines. Rhee & van Albada (1996)
 RBS2055 at 388 kpc, 88 az - (no lines)

Probably don't bother with non-detections?

3.32. NGC7817

$V_{sys} = 2309 \text{ km s}^{-1}$. Sightline equidistant but oppo-
 site NGC7798. Rhee & van Albada (1996)
 MRK335 at 343 kpc, 90 az (Lya at 1954, 2274)

3.33. UGC08146

$V_{sys} = 670 \text{ km s}^{-1}$. Small but isolated. Rhee & van
 Albada (1996)
 PG1259+593 at 114 kpc, 50 az (Lya at 646, 683)
 SBS1304+594 at 235 kpc, 15 az (no lines, low SN)

4. HALO ROTATION MODEL

In order to better understand how QSO sightlines
 probe intervening velocity structure we have developed a

simple halo gas rotation model. This model is seeded by
 an observed rotation curve (or whatever rotation curve-
 esque data suits ones fancy). This input curve is then
 interpolated and extended out to $2R_{vir}$ based on the av-
 erage velocity of the outer 1/2 radius. Next, we project
 this interpolated rotation curve onto a plane oriented to
 a faux QSO sightline identically to the input galaxy-QSO
 pair orientation. By stacking multiple rotation-planes in
 the galaxy z-axis direction, we then create a simple cylin-
 drical rotating halo model. Finally, each rotation-plane
 in the stack is projected onto the faux sightline. The
 result is a function representing the rotation velocity en-
 countered by the sightline as a function of velocity (or
 distance) along it.

For each galaxy-QSO pair we created 2 rotation mod-
 els: 1) a purely cylindrical halo extending $2R_{vir}$ in height
 and $3R_{vir}$ in radius, and 2) a cylindrical model extending
 $2R_{vir}$ in height and $3R_{vir}$ in radius with rotation veloci-
 ties which smoothly decline toward systemic based on a
 fitted NFW profile.

5. DISCUSSION

6. SUMMARY

This research has made use of the NASA/IPAC Ex-
 tragalactic Database (NED) which is operated by the
 Jet Propulsion Laboratory, California Institute of Tech-
 nology, under contract with the National Aeronautics
 and Space Administration. Based on observations with
 the NASA/ESA *Hubble Space Telescope*, obtained at the
 Space Telescope Science Institute (STScI), which is op-
 erated by the Association of Universities for Research
 in Astronomy, Inc., under NASA contract NAS 5-26555.
SALT ACKNOWLEDGEMENT. Spectra were re-
 trieved from the Barbara A. Mikulski Archive for Space
 Telescopes (MAST) at STScI. Over the course of this
 study, D.M.F. and B.P.W. were supported by grant AST-
 1108913, awarded by the US National Science Founda-
 tion, and by NASA grants *HST*-AR-12842.01-A, *HST*-
 AR-13893.01-A, and *HST*-GO-14240 (STScI).

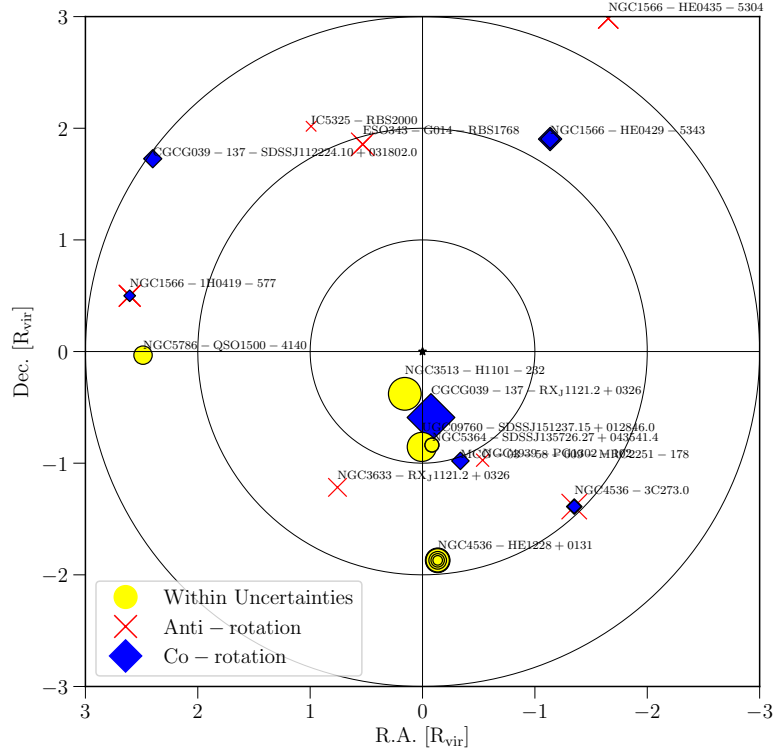

Figure 2. A map of the locations of each absorber normalized with respect to the galaxy virial radius. Concentric rings indicate distances of 1, 2 and 3 R_{vir} . All galaxies are rotated to $PA = 90$, such that their major axis' are horizontal. The color and style of each point indicates the line-of-sight velocity compared to that of the rotation of the nearby galaxy. Blue diamonds indicate co-rotation, red X's indicate anti-rotation, and yellow circles indicate cases where either is possible due to a combination of orientation and velocity uncertainties. The size of each point is scaled to reflect the EW of the absorber.
